ABSTRACT

A new ecological concrete was developed which can achieve CO₂ emission levels below zero by capturing CO₂ emitted from thermal power stations. This concrete is based on two typical features: one is the use of a special additive (dicalcium silicate γ phase: γ-2CaO•SiO₂) and coal-ash instead of cement. These materials have very low level of CO₂ emissions, and γ-2CaO•SiO₂ hardens concrete by reaction with CO₂. Another feature of this concrete is the capture of CO₂ contained in exhaust gas from thermal power stations. After this concrete is manufactured, it is placed into a curing chamber. The chamber is filled with exhaust gas, and CO₂ contained in the exhaust gas is captured in the concrete. The authors introduce materials and method of manufacturing and show the physical and chemical properties of this concrete in this paper.

Keywords: CO₂ emission, Carbonation curing, γ-2CaO•SiO₂, Exhaust gas

1. INTRODUCTION

The reduction of greenhouse gases has become a priority issue in various industries. According to the Kyoto Protocol, Japan is obligated to reduce greenhouse gas emissions estimated at 1,260 million tons in 1990 by 6% before 2012. As shown in Figure 1, CO₂ emissions in Japan have decreased gradually from 2007 (Ministry of the Environment, 2012). However, after the occurrence of the Great East Japan Earthquake in 2011, the tendency of this graph may change considerably. The electric industry accounts for
approximately 30% of the CO₂ emissions generated in Japan. Enhancement of thermal efficiency in power stations and expansion and diffusion of recyclable energies such as hydro power, solar power and wind power are being promoted vigorously.

On the other hand, some efforts are being made to reduce CO₂ emissions even in the concrete fields in Japan. (Sakai, 2010) “Optimization of structural types and construction methods” and “Effective use of by-products” were introduced in the “Recommendation of environmental performance verification for concrete structures (draft),” (JSCE, 2005).

A large amount of CO₂ is generated during the manufacturing process of cement. For this reason, using by-products such as fly ash or blast-furnace slag with a small amount of CO₂ emissions instead of cement is the main method of reducing CO₂ emissions in the concrete fields. For instance, according to the Japan Society of Civil Engineers (JSCE), the CO₂ emissions can be reduced about 15% by using fly-ash cement type B and approximately 40% by using blast-furnace cement type B.

Under these circumstances, the authors confirmed from past studies that a very dense matrix could be obtained by mixing in concrete a special additive called γ-2CaO·SiO₂ (hereafter “γ-C₂S”) as a major component, followed by carbonating the mixture forcibly (Watanabe, 2004). The authors have developed a new ecological concrete by using γ-C₂S instead of cement and by carbonation curing. γ-C₂S has a very low level of CO₂ emissions. Moreover, the new ecological concrete uses coal-ash instead of cement. As a result, CO₂ emissions of this concrete were reduced by half compared to ordinary concrete.

The authors have also developed a new ecological concrete by applying this “carbonation” technique to “CO₂ capture and storage to concrete” (Torichigai, 2010). When the concrete is manufactured, exhaust gas from thermal power stations is used as the source of supply of CO₂ for carbonation curing. It is considered that capturing CO₂ to concrete by carbonation curing leads to reduced CO₂ emissions from thermal power stations. More CO₂ is captured during the hardening process than CO₂ emission amounts originating from materials during the production of the ecological concrete. The total CO₂ emissions of the newly developed concrete could be brought down to below zero.

Materials used and the manufacturing method of new ecological concrete are introduced in this paper, and the physical properties of the concrete such as compressive strength, resistance to abrasion, and chemical properties are reported.

2. MATERIALS AND METHODS OF MANUFACTURING

2.1 Special additives γ-C₂S

Table 1. shows the chemical and physical properties of γ-C₂S. γ-C₂S consists of CaO and SiO₂ as the principal components, and the main mineral composition is gamma type calcium silicate. It is manufactured using by-product containing mainly Ca(OH)₂ and SiO₂ powder. γ-C₂S is a powdery material. Specific surface is a little bit coarser than portland cement. CO₂ emissions of γ-C₂S have been estimated in past studies (Morioka, 2010). There are many manufacturing methods, but the quantity of CO₂ generated during manufacture of the special

additive can be reduced by using by-product containing Ca(OH)\textsubscript{2} that generates smaller quantities of CO\textsubscript{2}. The quantity of CO\textsubscript{2} emitted during manufacture of $\gamma$-C\textsubscript{2}S is about one-fifth that of ordinary portland cement.

### 2.2 Materials and mix proportion

Properties of materials used in the new ecological concrete are shown in Table 2. In this paper, two types of mix proportion for the new ecological concrete are studied. One of the mix proportion type is concrete which is used for precast concrete blocks as shown in Fig.2 (left). Various examinations were conducted so that CO\textsubscript{2} emissions of used materials could be reduced as far as possible while required strength was satisfied, and the following conditions were adopted for mix proportion: Water binder (binder= HPC + BFS + $\gamma$-C\textsubscript{2}S + F) ratio is 48%, component ratio of binder is set at [OPC: BFS: $\gamma$-C\textsubscript{2}S: F = 24: 32: 24: 20], slump of the concrete is 8 cm, and the air content of the concrete is 4.5%.

Another mix proportion type is mortar which is used for interlocking blocks as shown in Fig. 2(right), and the following conditions were adopted as mix proportion: Water binder (binder= BB + $\gamma$-C\textsubscript{2}S + F) ratio is 30%, component ratio of binder set at [BB: $\gamma$-C\textsubscript{2}S: F = 67: 8: 25], slump of the mortar is 0 cm, and air content of the mortar is 8.0%. This mortar can de-molded after casting immediately.

Figure 2. Appearance of new ecological concrete (left) and mortar (right)
2.3 Manufacturing method of this concrete

After this concrete was mixed by concrete mixer, it was cast in forms. When the compressive strength reached 3.0 N/mm², the sample was de-molded, and carried to the carbonation curing chamber shown in Fig. 3. For quality control, a cylindrical specimen of φ10 cm × 20 cm in size was prepared, and the same curing method was applied. Exhaust gas from a thermal power station was supplied into the curing chamber for sealing after adjusting the temperature to 50°C and the relative humidity to 40%.

A phenomenon called “neutralization” occurs during reaction with CO₂ in the air in ordinary concrete. However, neutralization depth after 20-30 years may be only about 10 mm from the surface. In the new ecological concrete, a large quantity of CO₂ is absorbed immediately by controlling curing temperature and humidity, and by supplying CO₂ of high concentration contained in exhaust gas.

Moreover, temperature and humidity control system shown in Fig.3 can control the temperature and humidity of the curing chamber without electricity energy by using industrial steam or industrial water to heat exchanger. By using this system, CO₂ emissions during the manufacturing process of the new ecological concrete are reduced sharply. The concentration of CO₂ was measured and found to be between 15 and 20%. Sulfur oxides (SOx), and nitrogen oxides (NOx) is contained in the exhaust gas, and the concentration of SOx and NOx in the exhaust gas were several 10 ppm.

2.4 Experimental method

After the carbonation curing, some experimental tests were carried out. Carbonation depth, CO₂ contents, CO₂ emissions, and phase analysis of the new ecological concrete were measured to clarify the chemical characteristics of the concrete, and compressive strength was measured to clarify the physical characteristics of the concrete. Moreover, to show the feature of new ecological concrete, resistance to abrasion and leaching tests were carried out for the new ecological mortar blocks.

3. EXPERIMENTAL RESULTS FOR CONCRETE

3.1 Carbonation depth
Relationship between curing time and carbonation depth is shown in Fig. 4. Carbonation depth is measured based on JIS A 1152 “Method for measuring carbonation depth of concrete.” Carbonation depth of concrete which is cured with the same temperature, same humidity, and pure CO₂ gas of 20% concentration which is industrially manufactured, is also shown in this figure. Concrete cylindrical specimens of φ10 cm × 20 cm were fully carbonated in about 14 days regardless of the gas used, and carbonation speed was equivalent to that obtained using exhaust gas and industrial CO₂ gas. This figure shows that neither several 10 ppm NOx nor SOx included in exhaust gas influences carbonation depth and speed of this concrete.

3.2 CO₂ emission

The amount of captured CO₂ of the new ecological concrete after carbonation curing is shown in the Fig. 5. In this study, an inorganic carbon analyzer “coulometer” made in Japan by Ans Corporation was used as the analytical instrument, where CO₂ generated by dropping hydrochloric acid in a sample is collected into an absorbing liquid and CO₂ amount is quantified through a titration method. This device enables measurement of only inorganic carbon gasified due to decomposition with the acid (Higuchi, 2013). The amount of captured CO₂ in concrete, which is cured with the same temperature, same humidity, and pure CO₂ gas of 20% concentration which is industrially manufactured, is also shown in this figure. Moreover, the amount of captured CO₂ in normal concrete (Water binder ratio is 47%, using ordinary portland cement) cured in air for 6 months are shown in this figure.

Figure 5. Amount of capturing CO₂

Figure 6. Amount of CO₂ emission
Amount of captured CO₂ in concrete which is cured in 20% industrial CO₂ gas and cured in exhaust gas is equivalent, and the amount of captured CO₂ of these concretes increased as compared with normal concrete. It seems that normal concrete captured CO₂ in air, and the new ecological concrete captured CO₂ contained in industrial CO₂ gas or exhaust gas. This fact was verified when carbonation curing is applied using exhaust gas from thermal power stations, it is possible to capture a large amount of CO₂ contained in exhaust gas in concrete.

The CO₂ emission intensity values originated from materials used in this study are shown in Table 3. Based on these values, CO₂ emissions originating from materials during the production of these concretes were calculated. The calculated result was 85.7 kg/m³. The value obtained by subtracting the amount of captured CO₂ shown in Fig. 5 from the calculated CO₂ emissions based on Table 3, is shown in Fig. 6. According to this figure, CO₂ emission of the ecological concretes cured in industrial CO₂ gas or exhaust gas were reduced sharply compared with normal concrete. Moreover, it was clarified that when carbonation curing was performed using exhaust gas, the amount of captured CO₂ surpassed the CO₂ emission amount originating from the materials.

It has been verified that by choosing a combination of materials giving small amount of CO₂ emissions, and by applying carbonation curing through an appropriate method, a large amount of CO₂ can be captured in concrete, and the total CO₂ emissions including that originating from materials can be reduced to a negative value.

3.3 Compressive strength

The relationship between curing time and compressive strength is shown in Fig.7. Compressive strength is measured based on JIS A 1108. The compressive strength of the concrete cured at the same temperature, same humidity, and CO₂ gas of 20% concentration which contains neither NOx nor SOx instead of exhaust gas, is also shown in this figure. Compressive strength of concrete which is cured with exhaust gas at 14 days is slightly lower compared to concrete cured with industrial CO₂ gas. But compressive strength at 28 days of concrete cured with exhaust gas is equivalent to the compressive strength of concrete cured with industrial CO₂ gas. This figure shows that neither several 10 ppm NOx nor SOx in exhaust gas influences compressive strength of this concrete.

3.4 Phase analysis

The fractured samples of concrete cylindrical specimens which were cured with exhaust gas for 28 days, were subjected to XRD analysis. XRD-patterns of the concrete cured with exhaust gas for
14 days are shown in Fig. 8. The main minerals of this concrete are calcite, vaterite and SiO₂. It is considered that calcite and vaterite are precipitated by carbonation curing. Generally, it is known that calcite is precipitated when Ca(OH)₂ which is the main hydrate of concrete reacts with CO₂. In past studies, it was also known that vaterite precipitated alternatively when γ-C₂S reacted with CO₂ (Saito, 2008). This figure shows that γ-C₂S reacted with CO₂ satisfactorily. This figure also shows that Ca(OH)₂ does not exist in this concrete. It is seen that all Ca(OH)₂ of this concrete reacted with CO₂ by carbonation curing. Moreover, no mineral containing NOx or SOx was not found in this concrete. It is shown that NOx and SOx contained in exhaust gas do not affect the reaction of Ca(OH)₂ or γ-C₂S, which is included in this concrete with CO₂.

4. EXPERIMENTAL RESULTS FOR MORTAR BLOCK

4.1 Resistance to abrasion

Interlocking block is usually used for roads, such as driveways and sidewalks. Therefore, high resistance to abrasion is required in interlocking blocks. The resistance to abrasion of mortar was estimated by the abrasion test. Abrasion test was done based on ISO 9352:1995 “Plastics - Determination of resistance to wear by abrasive wheels”. Results of abrasion test are shown in Fig. 9. In this figure, the test results of normal interlocking block (water binder ratio is 30%, using blast-furnace cement type B) are also shown. This figure shows that the resistance to abrasion of the new ecological mortar is greater than that of the normal interlocking block. It is considered that calcite and vaterite are precipitated in this mortar by carbonation curing and the mortar become dense.

4.2 Leaching (efflorescence)

When manufacturing interlocking blocks, efflorescence occurs frequently. Since the appearance of the surface become worse when efflorescences are occurred, occurrence of efflorescence must be reduced as much as possible. The incidence of efflorescence when manufacturing normal interlocking blocks or new ecological mortar blocks is shown in Fig. 10. Appearances of both blocks are also shown in Fig. 10. It is seen that the incidence of efflorescence is small in the new ecological mortar compared to normal interlocking blocks. It is known that Ca(OH)₂ included in concrete and CO₂ in air react and efflorescence occurs. In the new ecological mortar, since all Ca(OH)₂ is changed to CaCO₃ by carbonation curing, it is considered that efflorescence has not occurred. Moreover, the pH value of this concrete is close to neutral (7-8) because this concrete is fully carbonated and Ca(OH)₂ does not exist. This concrete has high resistance to leaching of Calcium from concrete.
5. CONCLUSIONS

Materials and manufacturing method of new ecological concrete are introduced, and physical, chemical properties of this concrete are reported in this paper. In concluding, I should note that shown below.

(1) Carbonation speed, the amount of captured CO₂, and compressive strength of the new ecological concrete cured with exhaust gas were equivalent to those of the concrete cured with industrial CO₂ gas. It was clarified that neither several 10 ppm NOx nor SOx contained in exhaust gas influence carbonation speed, the amount of captured CO₂, and the compressive strength of new ecological concrete.

(2) After calculating CO₂ emission amount originated from raw materials, CO₂ balance related to concrete production was evaluated. As a result, by choosing powder compositions, and by applying the proper method of carbonation curing, the CO₂ emission amount including that originated from raw materials can be reduced to negative value.

(3) Resistance to abrasion of the new ecological mortar is greater than that of the general interlocking block. It is considered that calcite is precipitated in this mortar by carbonation curing and the mortar become dense.

(4) The incidence of efflorescence is small in the new ecological mortar compared to general interlocking block. In this mortar, since all Ca(OH)₂ has changed to CaCO₃ by carbonation curing, it is considered that efflorescence has not occurred.
